Abstract

This paper presents a new approach in application of the Fourier transform to the complex error function resulting in an efficient rational approximation. Specifically, the computational test shows that with only 17 summation terms the obtained rational approximation of the complex error function provides the average accuracy $10^{-15}$ over the most domain of practical importance $0 \leq x \leq 40,000$ and $10^{-4} \leq y \leq 10^2$ required for the HITRAN-based spectroscopic applications. Since the rational approximation does not contain trigonometric or exponential functions dependent upon the input parameters $x$ and $y$, it is rapid in computation. Such an example demonstrates that the considered methodology of the Fourier transform may be advantageous in practical applications.

Keywords: Fourier transform, complex error function, Faddeeva function, rational approximation

1. Introduction

The forward and inverse Fourier transforms can be defined as (Bracewell, 2000; Hansen, 2014)

$$F (\nu) = \mathcal{F} \{ f (t) \} (\nu) = \int_{-\infty}^{\infty} f (t) e^{-2\pi i \nu t} dt \quad (1a)$$

and

$$f (t) = \mathcal{F}^{-1} \{ F (\nu) \} (t) = \int_{-\infty}^{\infty} F (\nu) e^{2\pi i \nu t} d\nu, \quad (1b)$$

respectfully. Approximation theory based on the Fourier trigonometric series for functions or signals remains a topical subject in mathematical analysis and many new efficient methodologies have been reported in the recent scientific literature (see for example Mishra & Mishra, 2012; Mishra et al. 2013; Boyd, 2013).

In our recent publication (Abrarov & Quine, 2015d) we have shown that a sampling with the Gaussian function of the kind $he^{-(t/c)^2}/(c \sqrt{2})$ leads to the trigonometric approximations for the forward

$$F (\nu) = \mathcal{F} \{ f (t) \} (\nu) \approx he^{-\pi (\pi c)^2} \sum_{n=-N}^{N} f (nh) e^{-2\pi i n \nu h} \quad (2a)$$

and inverse Fourier transforms

$$f (t) = \mathcal{F}^{-1} \{ F (\nu) \} (t) \approx he^{-\pi (\pi c)^2} \sum_{n=-N}^{N} F (nh) e^{2\pi i n \nu h}, \quad (2b)$$

where $h$ is the step between two adjacent sampling points and $c$ is the fitting parameter, $e^{-2\pi i n \nu h} = \cos (2\pi n \nu h) - i \sin (2\pi n \nu h)$ and $e^{2\pi i n \nu h} = \cos (2\pi n \nu h) + i \sin (2\pi n \nu h)$. The parameters $h$, $c$ and $N$ in the equations (2a) and (2b) may be the same in the forward and inverse Fourier transforms only when we imply the most favorable conditions $h << 1$, $c << 1$ and $N >> 1$. In practical tasks, however, these conditions may be compromised in order to reduce the number of
the summation terms. As a result, these parameters may not be necessarily equal to each other in the forward and inverse Fourier transforms. Consequently, it is convenient to rewrite two equations above in form

\[ F(v) = \mathcal{F} \{ f(t) \} (v) \approx h_f e^{-\frac{x^2}{2}} \sum_{m=-M}^{M} f \left( mh_f \right) e^{-2\pi i m v h_f} \]

and

\[ f(t) = \mathcal{F}^{-1} \{ F(v) \} (t) \approx h_i e^{-\frac{x^2}{2}} \sum_{n=-N}^{N} F \left( nh_i \right) e^{2\pi i n t h_i}, \]

where \( h_f, c_f, M \) and \( h_i, c_i, N \) are the steps, the fitting parameters and the integers corresponding to the forward and inverse Fourier transforms, respectively.

The presence of the damping functions \( e^{-\frac{x^2}{2}} \) and \( e^{-\frac{x^2}{2}} \) in the equations above excludes periodicity of the approximated functions \( f(t) \) and \( F(v) \). Consequently, a solitary wavelet (or non-periodic pulse) can be effectively approximated in the Fourier transform. However, when we take \( c_f = c_i = 0 \), the right side of these equations become periodic with corresponding periods \( 1/h_f, 1/h_i \) and represent the Fourier-type expansion series as follows

\[ F(v) \approx h_f \sum_{m=-M}^{M} f \left( mh_f \right) e^{-2\pi i m v h_f}, \quad -\frac{1}{2h_f} \leq v \leq \frac{1}{2h_f}, \] (3a)

and

\[ f(t) \approx h_i \sum_{n=-N}^{N} F \left( nh_i \right) e^{2\pi i n t h_i}, \quad -\frac{1}{2h_i} \leq t \leq \frac{1}{2h_i}. \] (3b)

It should be noted that if the integral (1a) is not analytically integrable, then the function \( f(t) \) can be approximated by substituting equation (3a) into (3b). This substitution yields

\[
 f(t) \approx h_i \sum_{n=-N}^{N} \left[ h_f \sum_{m=-M}^{M} f \left( mh_f \right) e^{-2\pi i m n h_f} \right] e^{2\pi i n t h_i}
 = h_i h_f \sum_{n=-N}^{N} \sum_{m=-M}^{M} f \left( mh_f \right) e^{2\pi i m n h_f} e^{2\pi i n t h_i}
 = h_i h_f \sum_{n=-N}^{N} \sum_{m=-M}^{M} f \left( mh_f \right) e^{2\pi i n \left( t - m h_f \right)}, \quad -\frac{1}{2h_i} \leq t \leq \frac{1}{2h_i}.
\]

In this work we show a new application methodology of the Fourier transform to the complex error function. Due to representation of the complex error function as a rational approximation, it is rapid in computation. Furthermore, with only 17 summation terms the obtained rational approximation of the complex error function provides accuracy \( 10^{-15} \) over the most domain of practical importance \( 0 \leq x \leq 40,000/\pi \times 10^{-4} \leq y \leq 10^2 \) required for applications utilizing the HITRAN molecular spectroscopic database (Rothman et al., 2013).

2. Derivation

2.1 Function Overview

The complex error function, also known as the Faddeeva function or the Kramp function, can be defined as (Faddeyeva & Terent’ev, 1961; Gautschi, 1970; Abramowitz & Stegun, 1972; Armstrong & Nicholls, 1972; Schreier, 1992)

\[ w(z) = e^{-z^2} \left( 1 + \frac{2i}{\sqrt{\pi}} \int_0^{z} e^{t^2} dt \right), \]

where \( z = x + iy \) is the complex argument. The complex error function is a solution of the differential equation (Schreier, 1992)

\[ w'(z) + 2zw(z) = \frac{2i}{\sqrt{\pi}}, \]

with initial condition \( w(0) = 1 \).

The complex error function is closely related to a family of the special functions. Among them the most important one is the complex probability function (Armstrong & Nicholls, 1972; Schreier, 1992; Weideman, 1994)

\[ W(z) = PV \frac{i}{\pi} \int_{-\infty}^{0} \frac{e^{-z^2}}{t - z} dt \]
or

\[ W(x, y) = \text{PV} \int_{-\infty}^{\infty} \frac{e^{-t^2}}{(x + iy) - t} \, dt. \]

This principal value integral implies that the complex probability function has no discontinuity at \( y = 0 \) and \( x = t \). In particular,

\[ \lim_{y \to 0} W(x, y) = e^{-x^2} + \frac{2i}{\sqrt{\pi}} \text{daw}(x), \quad (4) \]

where \( \text{daw}(x) \) is the Dawson’s integral that will be briefly introduced later. There is a direct relationship between complex error function and complex probability function (Armstrong & Nicholls, 1972; Schreier, 1992)

\[ W(z) = w(z), \quad \text{Im}[z] \geq 0. \quad (5) \]

The real part of the complex probability function, denoted as \( K(x, y) \), is known as the Voigt function. Mathematically, the Voigt function represents a convolution integral of the Gaussian and Lorentzian distributions (Armstrong & Nicholls, 1972; Schreier, 1992; Letchworth & Benner, 2007; Pagnini & Mainardi, 2010; Abrarov et al., 2010)

\[ K(x, y) = \text{PV} \int_{-\infty}^{\infty} \frac{e^{-t^2}}{y^2 + (x - t)^2} \, dt, \]

where the principal value integral also implies that it has no discontinuity at \( y = 0 \) and \( x = t \). Specifically, from equation (4) it follows that

\[ \lim_{y \to 0} K(x, y) = e^{-x^2}. \]

At non-negative argument \( y \) the real part of the complex error function is also the Voigt function in accordance with identity (5). The Voigt function is widely used in many spectroscopic applications as it describes the line broadening effects (Edwards, 1992; Quine & Drummond, 2002; Christensen et al., 2012; Berk, 2013; Quine & Abrarov, 2013). Therefore, the application of the complex error function is very significant in quantitative spectroscopy.

Other closely related functions are the error function of complex argument (Schreier, 1992)

\[ w(z) = e^{-z^2} \text{erfc}(-iz) = e^{-z^2} \left[ 1 - \text{erf}(-iz) \right] \iff \text{erf}(z) = 1 - e^{-z^2} w(iz), \]

the plasma dispersion function (Fried & Conte, 1961)

\[ Z(z) = \text{PV} \int_{-\infty}^{\infty} \frac{e^{-t^2}}{t-z} \, dt = i \sqrt{\pi} w(z) \]

the Dawson’s integral (Cody, 1970; McCabe, 1974; Rybicki, 1989; Boyd, 2008; Abrarov & Quine, 2015c)

\[ \text{daw}(z) = e^{-z^2} \int_{0}^{z} t \, dt = \sqrt{\pi} \frac{e^{-z^2}}{2i} + \frac{w(z)}{2i}, \]

the Fresnel integral (Abramowitz & Stegun, 1972; McKenna, 1984)

\[ F_{\psi}(z) = \int_{0}^{z} e^{i\psi z^2} \, dt = (1 + i) \left[ 1 - e^{i\psi z^2} w \left( \sqrt{\pi} (1 + i) z/2 \right) \right]/2 \]

and the normal distribution function (Weisstein, 2003)

\[ \Phi(z) = \frac{1}{\sqrt{2\pi}} \int_{0}^{z} e^{-t^2/2} \, dt = \frac{1}{2} \text{erf} \left( \frac{z}{\sqrt{2}} \right) \]

\[ = \frac{1}{2} \left[ 1 - e^{-z^2/2} w \left( \frac{iz}{\sqrt{2}} \right) \right]. \]
It is not difficult to show that the complex error function can be represented in an alternative form (see equation (3) in (Srivastava & Miller, 1987) and (Srivastava & Chen, 1992), see also Appendix A in (Abrarov & Quine, 2015c) for derivation)
\[ w(x, y) = \frac{1}{\sqrt{\pi}} \int_{0}^{\infty} \exp(-t^2/4) \exp(\pm yt) \exp(ixt) \, dt. \] (6)

This representation of the complex error function will be used for derivation of a rational approximation.

2.2 Rational Approximation

In our recent publications we have shown a new technique to obtain a rational approximation for the integrals of kind (Abrarov & Quine, 2014; Abrarov & Quine, 2015b)
\[ \int_{0}^{\infty} e^{-t^2} f(t) \, dt. \]

We apply this approach together with the Fourier transform methodology discussed above in the Introduction.

We can use either of equation (3a) or (3b). For example, we may choose the equation (3b) corresponding to the inverse Fourier transform. Consider the function \( f(t) = e^{-t^2/4} \). Let us first its forward Fourier transform by substituting \( f(t) = e^{-t^2/4} \) into equation (1a). These leads to
\[ F(v) = \int_{-\infty}^{\infty} e^{-t^2/4} e^{-2\pi ivt} \, dt = 2 \sqrt{\pi} e^{-(2\pi v)^2}/\sqrt{\pi}. \]

Now substituting \( 2 \sqrt{\pi} e^{-(2\pi v)^2} \) into equation (3b) yields the following approximation for the exponential function
\[ e^{-t^2/4} \approx 2 \sqrt{\pi} \sum_{n=-N}^{N} e^{-2\pi i n h_i} \cos(2\pi n h_i), \quad -\frac{1}{2h_i} \leq t \leq \frac{1}{2h_i}, \] or
\[ e^{-t^2/4} \approx 2 \sqrt{\pi} \sum_{n=-N}^{N} e^{-2\pi i n h_i} \cos(2\pi n h_i), \quad -\frac{1}{2h_i} \leq t \leq \frac{1}{2h_i}. \] (7)

Taking into account that
\[ e^{-2\pi i 0 h_i} \cos(2\pi 0 h_i) = 1 \]
and
\[ \sum_{n=-N}^{-1} e^{-2\pi i n h_i} \cos(2\pi n h_i) = \sum_{n=1}^{N} e^{-2\pi i n h_i} \cos(2\pi n h_i) \]
the approximation (7) can be simplified as given by
\[ e^{-t^2/4} \approx 2 \sqrt{\pi} h_i \left[ 1 + 2 \sum_{n=1}^{N} e^{-2\pi i n h_i}\cos(2\pi n h_i) \right], \quad -\frac{1}{2h_i} \leq t \leq \frac{1}{2h_i}. \] (8)

The right side limitation \( t \leq 1/(2h_i) \) along the positive \( t \)-axis in equation (8) can be readily excluded by multiplying both its sides to \( \exp(-\sigma t) \) if a constant \( \sigma \) is positive and sufficiently large. This can be explained by considering Fig. 1 that shows two functions computed according to right side of equation (8) at \( \sigma = 0.1 \) (blue curve) and \( \sigma = 0.2 \) (red curve). For example, at \( \sigma = 0.1 \) we can observe two additional peaks at \( 1/h_i \) and \( 2/h_i \) (blue curve). However, as \( \sigma \) increases the additional peaks are suppressed stronger to zero due to multiplication to the damping exponential function \( \exp(-\sigma t) \). As a result, at \( \sigma = 0.2 \) only a single additional peak at \( 1/h_i \) remains visible (red curve). By \( \sigma \geq 1 \) all additional peaks completely vanish and, therefore, do not contribute to error in integration. Consequently, if the constant \( \sigma \) is large enough, say approximately equal or greater than 1, we can write the approximation
\[ e^{-t^2/4} e^{-\sigma t} \approx 2 \sqrt{\pi} h_i \left[ 1 + 2 \sum_{n=1}^{N} e^{-2\pi i n h_i}\cos(2\pi n h_i) \right] e^{-\sigma t}, \quad \sigma \geq 1, \]
that remains always valid without any limitation along the positive $t$-axis. Assuming $y \geq 0$ we, therefore, can write now

$$e^{-t^2/4}e^{-\sigma t} \approx 2 \sqrt{\pi} h \left[ 1 + 2 \sum_{n=1}^{N} e^{-\left(2\pi n \sigma h\right)^2} \cos (2\pi n \sigma h) \right] e^{-\left(y + i\sigma \right) t}, \quad \sigma \geq 0.$$  

(9)

Since $e^{-t^2/4}e^{-\sigma t} = e^{-\left(t^2+2\sigma^2\right)/4}e^{-\left(y+\sigma \right) t}$ from approximation (9) we obtain

$$e^{-t^2/4}e^{-\sigma t} \approx 2 \sqrt{\pi} h \left[ 1 + 2 \sum_{n=1}^{N} e^{-\left(2\pi n \sigma h\right)^2} \cos (2\pi n \sigma h) (t - 2\sigma) \right] e^{-\left(y+\sigma \right) t}, \quad \sigma \geq 0.$$  

(10)

Once again, due to presence of the rapidly damping exponential multiplier $e^{-\left(y+\sigma \right) t}$ this approximation is valid without any limitation along the positive $t$-axis. As the peak of the function $e^{-\left(t^2+2\sigma^2\right)/4}$ is shifted towards right with respect to the origin, we may regard to the value $\sigma$ as the shift constant.

Finally, substituting approximation (10) into integral (6) yields

$$w(z) \approx i \frac{2\pi e^{\sigma^2}h}{z + i\sigma} + \sum_{n=1}^{N} A_n - i(z + i\sigma) B_n \frac{1}{C_n - (z + i\sigma)^2},$$  

(11)

where

$$A_n = 8\pi h^2 i n e^{\sigma^2 - (2\pi n \sigma)^2} \sin (4\pi n \sigma) \right),$$

$$B_n = 4\pi h^2 e^{-\left(2\pi n \sigma \right)^2} \cos (4\pi n \sigma)$$

and

$$C_n = 2\pi h n.$$

As the expansion coefficients $A_n$, $B_n$ and $C_n$ are independent of the argument $z$, the obtained equation (11) is a rational approximation.

In algorithmic implementation it is more convenient to use $\psi$-function defined as

$$\psi(z) = i \frac{2\pi e^{\sigma^2}}{z} + \sum_{n=1}^{N} A_n - i B_n \frac{1}{C_n - z^2},$$  

(12)

$$\Rightarrow w(z) \approx \psi(z + i\sigma).$$
2.3 Computational Procedure and Error Analysis

Due to a remarkable property of the complex error function (McKenna, 1984; Zaghloul & Ali, 2011)

\[ w(-z) = 2e^{-z^2} - w(z), \]  
(13)

it is sufficient to consider only I and II quadrants in order to cover the entire complex plane. This can be seen explicitly by representation of the identity (13) in form

\[ w(\pm x, -|y|) = 2e^{-((\pm x + iy)^2)} - w(\mp x, +|y|). \]

Thus, if the parameter \( y \) is negative we can simply take it by absolute value and then compute the complex error function according to right side of this equation. Therefore, further we will always assume that \( y \geq 0 \).

When the argument \( z \) is large enough by absolute value, say \(|x + iy| > 15\), we can truncate the Laplace continued fraction (Gautschi, 1970; Jones & Thron, 1988)

\[ w(z) = \frac{1}{2} \frac{1}{z} \frac{3/2}{z} \frac{2}{z} \frac{5/2}{z} \frac{3}{z} \frac{7/2}{z} \ldots, \quad \mu_0 = i/\pi. \]

Approximation based on the Laplace continued fraction is rapid in computation. However, its accuracy deteriorates as the argument \( z \) decreases by absolute value.

There are different approximations for computation of the narrow-band domain \( 0 \leq x \leq 15 \cap 10^{-6} \leq y \leq 10^4 \) (Abrarov & Quine, 2014; Amanou, 2013; Abrarov & Quine, 2015a). We can apply, for example, an approximation proposed in our recent work (Abrarov & Quine, 2014)

\[ w(x, y \ll 1) \approx \left( 1 - \frac{y}{y_{\min}} \right) e^{-x^2} + \frac{y}{y_{\min}} K(x, y_{\min}) + iL(x, y_{\min}), \quad y_{\min} \ll 1, \]

where \( L(x, y_{\min}) = \text{Im} [w(x, y_{\min})] \) and \( y_{\min} \) can be taken equal to \( 10^{-5} \). It has been shown that this approximation can provide accuracy better than \( 10^{-9} \) over the narrow-band domain \( 0 \leq x \leq 15 \) and \( 0 \leq y \leq 10^{-6} \).

The domain \(|x + iy| \leq 15 \cap y \geq 10^{-6}\) is the most difficult for computation. Nevertheless, with only 17 summation terms (at \( N = 16 \)) the proposed rational approximation (12) covers this domain providing high-accuracy and rapid computation. In computational procedure we have to choose properly the margin value \( y_{\text{m}} \) for the exponential function \( e^{-((x+iy)^2)} \) that appears from the forward Fourier transform \( F(\nu) = 2\sqrt{\pi}e^{-(2\pi\nu)^2} \). As it has been justified by Melone et al. 1988, the margin value

---

![Figure 2. The logarithm of the relative error \( \log_{10}A_{Re} \) for the real part of the rational approximation (12) over the domain \( 0 \leq x \leq 15 \cap 10^{-6} \leq y \leq 10^4 \).](image-url)
for integration involving the exponential function $e^{-t^2}$ can be taken as $t = t_m = 6$. We can use this result in order to determine the required value by solving the following equation with respect to the variable $v$ as follows

$$e^{-((2v)^2)} = e^{-t^2} \Rightarrow (2v)^2 = 36.$$  

There are two solutions for this equation $v_{1,2} = \pm 6/(2\pi)$. Consequently, the margin value for the exponential function $e^{-((2v)^2)}$ can be taken as $v_m = 6/(2\pi)$. As a parameter $h_i$ is the step between two adjacent sampling points along positive $v$-axis (see Abrarov & Quine 2015d for details), its value can be calculated as $h_i = v_m/N$. Taking $N = 16$ we can find that $h_i = v_m/16 \approx 5.968310365946075 \times 10^{-2}$.

In order to quantify the accuracy of the rational approximation (12) we may define the relative errors

$$\Delta_{Re} = \left| \frac{\text{Re}[w_{ref}(x,y)] - \text{Re}[w(x,y)]}{\text{Re}[w_{ref}(x,y)]} \right|$$

and

$$\Delta_{Im} = \left| \frac{\text{Im}[w_{ref}(x,y)] - \text{Im}[w(x,y)]}{\text{Im}[w_{ref}(x,y)]} \right|,$$

where $w_{ref}(x,y)$ is the reference, for the real and imaginary parts, respectively. The highly accurate reference values can be generated by using, for example, Algorithm 680 (Poppe & Wijers, 1990a; Poppe & Wijers, 1990b), recently published Algorithm 916 (Zaghloul & Ali, 2011) or C++ code from the RooFit package, CERN’s library (Karbach et al., 2014).

Figure 2 shows $\log_{10}\Delta_{Re}$ for the real part of the complex error function computed over the domain $0 \leq x \leq 15$ and $10^{-6} \leq y \leq 15$ at $N = 16$, $\sigma = 1.5$ and $h_i = 5.968310365946075 \times 10^{-2}$. As we can see from this figure, the rational approximation (12) provides accuracy $10^{-15}$ (blue color) over the most of this domain. Although accuracy deteriorates with decreasing $y$, it remains better than $10^{-9}$ (red color) in the range $10^{-4} \leq y \leq 10^{-6}$. This indicates that at the same $N = 16$ the accuracy of the rational approximation (12) is by several orders of the magnitude higher than the accuracy of the Weideman’s rational approximation (see equation 38(I) in Weideman, 1994).

Figure 3 illustrates $\log_{10}\Delta_{Im}$ for the imaginary part of the complex error function also computed over the domain $0 \leq x \leq 15$ and $10^{-6} \leq y \leq 15$ at $N = 16$, $\sigma = 1.5$ and $h_i = 5.968310365946075 \times 10^{-2}$. One can see that in the imaginary part the accuracy is also highly accurate $10^{-15}$ (blue color) over the most domain. There is only a small area $0 \leq x < 1$ and $10^{-6} \leq y \leq 10^{-4}$ near the origin where the accuracy deteriorates as the parameters $x$ and $y$ both tend to zero. Nevertheless, the accuracy in this area still remains high and better than $10^{-9}$ (red color).
The computational test reveals that with only 17 summation terms (at \( N = 16 \)) the rational approximation (12) alone can cover the entire HITRAN domain \( 0 \leq x \leq 40,000 \cap 10^{-4} \leq y \leq 10^2 \) providing average accuracy \( 10^{-15} \) for an input array consisting of \( 3 \times 10^7 \) elements. Algorithmic implementation of the rational approximation (12) results to the same computational speed as that of described in our recent work where we proposed a sampling by incomplete cosine expansion of the sinc function to approximate the complex error function (Abrarov & Quine, 2015b).

A Matlab subroutine code that covers the HITRAN domain with high-accuracy is presented in Appendix A.

3. Conclusion

We present a new efficient rational approximation to the complex error function by application of the Fourier transform that provides computationally rapid and highly accurate results. The computational test we performed with only 17 summation terms shows that the accuracy of the rational approximation of the complex error function is \( 10^{-15} \) over the most domain of practical importance. In particular, the proposed rational approximation of the complex error function alone can cover with high accuracy the entire domain \( 0 \leq x \leq 40,000 \cap 10^{-4} \leq y \leq 10^2 \) required for the HITRAN-based spectroscopic applications.
