Abstract

In Malaysia, the incumbent WiMAX operator utilises the bands of 2360-2390MHz to provide broadband services. Like all Radio Frequency (RF), WiMAX is susceptible to path loss. In this paper, field strength data collected in Cyberjaya, Malaysia is used to calculate the path loss suffered by the WiMAX signals. The measured path loss is compared with the theoretical path loss values estimated by the COST-231 Hata model, the Stanford University Interim (SUI) model and the Egli model. The best model to estimate the path loss based on the path loss exponents was determined to be the COST-231 Hata model. From this observation, an optimised model based on COST-231 Hata parameters is developed to predict path loss for suburban and open urban environments in the 2360-2390MHz band. The optimised model is validated using standard deviation error analysis, and the results indicate that the new optimised model predicts path loss in both suburban and open urban environments with very low standard deviation errors of less than 4.3dB and 1.9dB respectively. These values show that the model optimisation was done successfully and that the new optimised models will be able to determine the path loss suffered by the WiMAX signals more accurately. The optimised model may be used by telecommunication providers to improve their service.

Keywords: Model Optimisation, Path Loss Models, Path Loss Exponents, WiMAX

1. Introduction

In Malaysia, incumbent WiMAX operator Packet One Networks (P1) Sdn. Bhd. utilises the bands of 2360-2390MHz to provide broadband services. Fixed WiMAX services are beneficial to the development of broadband used by consumers and small businesses while mobile WiMAX may be used for mobile services being provisioned by existing fixed-line carriers that do not own a 3G spectrum to provide Voice-over-IP (VoIP) or mobile entertainment services [Senza Filli Consulting, 2005].

Non-Line of Sight (NLOS) between a transmitter and a receiver in a wireless link will introduce multipath, which decreases the signal strength and introduces a subsequent increase in the receiver Bit Error Rate (BER) [Rappaport, T.S., 2002]. The path loss may differ in severity depending on the terrain and whether it is a rural, suburban or urban environment [Rappaport, T.S., 2002]. To increase the robustness of the transmitted information, engineers need to estimate the path loss introduced by a terrain over which the signal will propagate to sufficiently compensate for the power lost during signal propagation. Existing path loss models may be used to estimate this path loss, but it is ideal to develop an optimised model to use over a certain terrain in a particular band for faster transmitter power estimation.

In a previous study, Abhayawardhana *et al.* (2005) had conducted a feasibility study on the use of empirical models to predict path loss in BWA in the 3.5GHz band. Similar studies were also conducted by Rial *et al.* (2007) and Belloul *et al.* (2009).

Cyberjaya, in the district of Sepang, Selangor, has a mostly suburban terrain profile. In the recent years, Cyberjaya's natural suburban terrain profile has seen a rapid increase in the construction of three to four storey buildings that cater for the booming multinational companies here [Town & Country Planning Department, Malaysia, 2000]. These buildings, along with a multitude of wide roads, car parks and pedestrian pavements, have given rise to an environment which is slightly more than suburban. For this study, the terrain profile where the field testing was conducted was categorized carefully to be either "open urban" (multiple-story buildings

situated rather close to roads and car parks) or suburban (small hillocks with medium height trees) .The "open urban" profile is not considered to be the typical urban environment where skyscrapers and high rise buildings are packed close to each other.

In this paper, two optimised models to predict path loss for WiMAX signals in the 2360-2390MHz based on the COST-231 Hata model [COST Action 231, 1999] will be introduced. The optimised path loss models will be developed based on comparison between the measured path loss and the path loss estimated by the COST-231 Hata model. The COST-231 Hata model is selected because it showed the best agreement with the measured path loss in terms of path loss exponent, as compared to the Stanford University Interim SUI model introduced by Erceg,V. & Hari, K.V. S. (2001) and the Egli path loss model introduced by Egli (1957). The performances of these optimised models in estimating the path loss in the 2360-2390MHz band in both suburban and open urban environments are validated using standard deviation errors analysis.

2. Data collection and field setup

The base station (BS) in the Multimedia University, herein to be known as MMU BS, is situated 23m above ground level and has four WiMAX Base Stations (WBS) and serves a mix of open urban and suburban environments. Each WBS has a transceiver sectorized antenna which transmits in vertical polarization. The Customer Premise Equipment (CPE) used is a vertically polarized directional antenna with a 50° beamwidth. It was mounted on a makeshift mast, and was adjustable to 2m and 4 m heights (Figure 1). The field strength was observed using a spectrum analyzer at CPE heights of 2m and 4m for the duration of 1 minute and was recorded at every 10s interval.

The field testing was conducted within a 1km radius from the site, which is the estimated coverage of the MMU BS (Figure 2). The field strength was collected along the Line of Sight (LOS) of each WBS. At each measurement location, a Global Positioning System (GPS) was used to establish the location of the CPE and a compass was used to confirm that the antenna was facing towards the LOS path of the selected WBS. The measurements were taken at every 50m radial increment within the coverage hexagon (Figure 2). Due to geographical limitations caused by dense jungle, the maximum radial increment measurements recordable at the 270° WBS are 500m.

At each measurement location, the terrain profile was observed and categorised to be either suburban or open urban. All the field data from the four WBSs was then collectively separated to either suburban or open urban data and tabulated for the ensuing analysis.

3. Path loss models

3.1 Egli model

The Egli model is suitable for use in mobile systems in the bands of 3MHz- 3GHz and is normally used when there is LOS between one fixed antenna and one mobile antenna [Egli, 1957]. This model is selected for this study as the Egli model can be used for path loss prediction in the frequency range selected for this study.

The Egli path loss is calculated using (1) [Egli, 1957]

$$PL(dB) = G_B G_M \left[\frac{h_B}{d^2} h_M\right]^2 \left[\frac{40}{f}\right]^2 \tag{1}$$

where G_B is the gain of the BS antenna, G_M is the gain of the CPE, h_B is the height of the BS antenna from ground level, h_M is the height of the CPE, d is the receiver distance from the BS and f is the operating frequency of the CPE in MHz. The Egli model can be used when there is propagation over irregular terrain [Egli, 1957]. It should be noted that the Egli model does not provide correction factors for different environments.

3.2 COST-231 Hata model

The COST-231 Hata model is an extension of the Hata-Okumura model developed by Hata(1981) from the original Okumura path loss model [Okumura, 1968] and is used for the prediction of path loss for mobile wireless systems in urban environments. Correction factors for the use of this model in suburban environments are provided in [Abhayawardhana *et al.*, 2005]. This model was developed for use in 1500-2000MHz with CPE heights up to 10m and transmitter heights of 30-200m [Hata, 1981]. However, due to its simplicity and extensive usage, this model is selected for this study in the 2360-2390MHz band. Furthermore, this model is the basis for the Standard Propagation Model which is used for path loss modelling in WiMAX systems [Asztalos, 2008].

The COST-231 Hata model path loss is calculated using (2) [COST Action 231, 1999]

$$PL(dB) = 46.3 + 33.9 \log_{10}(f) - 13.82 \log_{10}(h_b) - ah_m + (44.9 - 6.55 \log_{10}(h_b)) \log_{10}d + c_m \quad (2)$$

where f is the frequency in MHz, d is the distance between BS and CPE antennae in km and h_b is the BS antenna height above ground level in meters.

The correction parameter ah_m is defined by (3) and (4) for urban and suburban environments respectively [Abhayawardhana *et al.*, 2005]. The correction parameter, c_m is given as $c_{m(urban)} = 3$ dB and $c_{m(suburban)} = 0$ dB [Abhayawardhana *et al.*, 2005].

$$ah_m = 3.2 \left(log_{10}(11.75H_r) \right)^2 - 4.97 \tag{3}$$

$$ah_m = (1.1\log_{10} f - 0.7)H_r - (1.56\log_{10} f - 0.8)$$
(4)

where H_r is the height of the CPE antenna in meters.

3.3 Stanford University Interim (SUI) model

The SUI model was developed under the Institute of Electrical and Electronics Engineers (IEEE) 802.16 working group for prediction of path loss in urban, suburban and rural environments [Erceg, V. & Hari, K. V. S., 2001]. The applicability of this model in the 2.3GHz band has not been validated. However, due to the availability of correction factors for the operating frequency, this model is selected for this study.

The SUI model path loss is calculated using (5) [Erceg, V. & Greenstein, L. J., 1999]

$$PL(dB) = A + 10\gamma \log_{10}\left(\frac{d}{d_o}\right) + X_f + X_h + s$$
(5)

where $d_o = 100$ m, d is the distance between BS and CPE antenna in meters, and s is a log-normally distributed factor used to account for tree and clutter shadowing. The values given for s in [9] are between 8.2dB and 10.6dB.

The path loss exponent for the SUI model, γ , is determined from constants (Table 1), which were developed through studies done by Erceg, V. & Greenstein, L. J. (1999). In this model, three types of terrains are used. This paper does not show the constants for Terrain C which depicts rural conditions. Terrain A is used for maximum path loss, depicting urban conditions, while terrain B is used for hilly terrains with light tree densities, depicting suburban conditions.

The path loss exponent, γ is determined by (6) [Erceg, V. & Greenstein, L. J., 1999]

$$\gamma = a - bh_b + \frac{c}{h_b} \tag{6}$$

where h_b is the height of the BS in meters and should be between 10m and 80m above ground level.

Parameter A is known as the intercept parameter [Erceg, V. & Greenstein, L. J., 1999] and is defined as

$$A = 20 \log_{10} \left(\frac{4\pi d_0}{\lambda}\right) \tag{7}$$

The SUI model also provides correction factors for the operating frequency, X_f , and the CPE antenna height, X_H , that can be found using (8) and (9) [Erceg, V. & Hari, K. V. S., 2001],

$$X_f = 6.0 \log_{10} \left(\frac{f}{2000} \right) \tag{8}$$

$$X_{H} = -10.8 \log_{10} \frac{H_{r}}{2000} \text{ for Terrains A and B}$$
(9)

where H_r is the CPE antenna height in meters and f is the operating frequency in MHz.

4. Measured path loss determination

The rate of propagation path loss with respect to a distance is shown by the path loss exponent. If the path loss exponent value is 2, then the environment propagation characteristic is close to free space propagation [Abhayawardhana *et al.*, 2005], or one that has less clutter. A path loss of 2- 4 indicates an environment that is urban [Rao *et al.*, 2000].

The path loss exponent is determined using (10) [Wikipedia, 2010],

$$PL(dB) = 10n \log_{10} d \tag{10}$$

where d is the distance from the transmitter and n is the path loss exponent. The equation given in (10) can be manipulated to determine the value of the path loss exponent of an environment. From (10), when a graph of path loss is plotted against the distance (dB), then the path loss exponent, n, can be determined by calculating the slope of this graph.

The path loss at a given location with respect to the path loss at a reference distance, d_o , may be determined using the Least Square (LS) regression analysis shown in (11) [Abhayawardhana *et al.*, 2005],

$$PL_d(dB) = PL_{d_o} + 10nlog_{10}\left(\frac{d}{d_o}\right)$$
(11)

where d_o is the reference point at 100m and *n* is the path loss exponent. The path loss exponent obtained from the slope of the Path Loss (dB) versus log *d* graph using (10) is substituted into (11) to determine the actual (measured) path loss of the area within 1km from the MMU BS.

The measured path loss (dB) was then plotted against the distance (Figure 3) and the slope was calculated to determine the path loss exponents [Wikipedia, 2010] in open urban and suburban environments for CPE heights of 2m and 4m.

The measured Received Signal Strength (RSS), as well as the calculated path loss using (1), (2), (5) and (11) is presented at the end of this paper (Table 2).

When the path loss is plotted against distance (Figure3), it was shown that path loss increased as the distance between the transmitter and the receiver is increased and that the path loss at a given distance is more in open urban environments than in suburban environments. Higher path loss is expected to be experienced by a CPE which is further away from the BS because the signal experiences more multipath fading as it propagates further away from the transmitter [Rappaport, 2002]. Higher path loss is also expected in open urban conditions because the clutter of the buildings will cause multipath fading and signal strength deterioration, in comparison to suburban conditions in which a LOS between transmitter and receiver may exist and allow the signal to propagate without suffering from diffractions, reflections, absorption and scattering [Anderson, 2003]. The path loss exponents found from the graphs (Figure 3) are summarized (Table 3) and compared against the theoretical path loss exponents which are calculated from the path loss models.

5. Best model selection

The path loss estimated by the SUI, COST-231 Hata and Egli models are calculated, and plotted against distance on the same graph as that of the measured path loss (Figures 4 and 5).

The path loss exponents found from the slopes of these graphs (Figures 4 and 5) are subsequently summarised (Table 4). The summary (Table 4) shows that the SUI and Egli models over-predict the path loss exponents of fixed WiMAX receivers in the suburban and open urban environments in the 2360-2390MHz band. For both open urban and suburban environments, the path loss exponent estimated by the COST-231 Hata model is in closest agreement with the LS analysis, which shows the actual path loss characteristics in Cyberjaya. This is especially true for the open urban environment. Based on this, the COST-231 Hata model is selected as the best model for optimisation.

Rao *et al.*, (2000) states that the standard deviation of error between the measured path loss and the path loss predicted can be estimated by (12)

$$PL_{error} = |PL_{measured} - PL_{model}| \tag{12}$$

where PL_{error} is the standard deviation of measured path loss, $PL_{measured}$, with the estimated path loss of models, PL_{model} . The standard deviation of error analysis will be used to analyse the performance of the new path loss models optimised from the existing COST-231 Hata path loss model.

6. COST-231 Hata model optimisation

Based on closest agreement with measured path loss exponents (Table 4), the COST-231 Hata model is selected as a basis for optimisation to develop a new model for the prediction of path loss for fixed WiMAX receivers in the 2360-2390MHz band. This section of the paper describes how the COST-231 Hata model is first optimised to match the measured path loss and then a comparison analysis of the performance of the new optimised model is madr against the measured path loss and the path loss estimated by the COST-231 Hata model.

6.1 Optimisation of measured data into COST-231 Hata model

The optimised model is developed based on the frequency of 2375MHz, which is the center frequency for the band of 2360-2390MHz. The height of the BS is taken as 23.6095m, which is the height of the building plus the height of half of the sectorised antenna length.

The COST-231 Hata model equation as shown by (2) of this paper which consists of three basic elements like in any other empirical propagation models, as described by Jacques, L. & Michel, S., (2000). The entire equation can be grouped into the initial offset parameter, E_o , the initial system design parameter, E_{sys} , and the slope of the model curve, β_{sys} .

The COST-231 Hata model from (2) can be expressed by (13), (14) and (15).

$$E_o = 46.3 - ah_m + c_m \tag{13}$$

$$E_{svs} = 33.9 \log_{10}(f) - 13.82 \log_{10}(h_b) \tag{14}$$

$$\beta_{sys} = (44.9 - 6.55 \log_{10}(h_b)) \log_{10} d \tag{15}$$

where total path loss is given by Jacques, L. & Michel, S.,(2000) as

$$PL(dB) = E_o + E_{sys} + \beta_{sys} \tag{16}$$

The path loss calculated from the measured data and the COST-231 Hata model are plotted and a simple logarithmic curve is used to plot the differences between the measured path loss and the path loss estimated by the COST-231 Hata model (Figures 6 and 7). The new logarithmic curve was subsequently presented as the optimised models. The new logarithmic curves, entitled "optimised model" (Figures 6 and 7) are in the form of

$$y = a \ln(x) + b \tag{17}$$

Based on (17), y is taken as the path loss (PL) and ln(x) depicts the relationship of distance from transmitter in meters. a is taken to be the β_{sys} and b is taken to be a cumulative of E_o and E_{sys} .

Based on the explanations subsequent to (17), two new equations (18) and (19) are presented as optimised models for the prediction of path loss in suburban and open urban environments respectively in the 2360-2390MHz.

An optimised model for predicting path loss for WiMAX based on COST-231 Hata model for suburban environment in 2360-2390MHz is presented as

$$PL(dB) = 36.2 + 9.467 \ln(x) \tag{18}$$

An optimised model for predicting path loss for WiMAX based on COST-231 Hata model for open urban environment in 2360-2390MHz is presented as

$$PL(dB) = 8.595 + 14.53\ln(x) \tag{19}$$

6.2 Optimised model performance analysis

The path loss is calculated using (18) and (19) and plotted against the measured path loss and the COST-231 Hata predicted path loss (Figures 8 and 9). Accordingly, the new path loss exponent estimated from the slopes of these figures for the optimised model in the suburban and open urban environments are summarised (Table 5).

In the suburban environment, the path loss estimated by the optimised model follows the measured path loss closely (Figure 8). Based on the summary of path loss exponents (Table 5), the path loss exponent predicted by the optimised model is lower than the measured path loss exponent for CPE heights of 2m and 4m. However, it can be concluded that the prediction of the optimised model (Table 5) increases in accuracy as the CPE height is increased.

In the open urban environment, the path loss estimated by the optimised model follows the measured path loss closely (Figure 9). Based on the summary (Table 5), the path loss exponent predicted by the optimised model is almost the same as the measured path loss exponent for CPE at 2m. For CPE at 4m, the predicted path loss exponent from the optimised model is higher than the measured path loss. This indicates that the accuracy of the optimised model's prediction in terms of path loss exponent reduces as the CPE height is increased.

A standard deviation error analysis is done and summarised (Table 6) to validate the performance of the optimised models. In the suburban environment, the standard deviation of error between measured and predicted path loss ranges from 0.3-4.3dB and 1.1-4.2dB for CPE heights of 2m and 4m respectively. It can be seen that the accuracy of the prediction by the optimised models increases with the CPE distance from the transmitter. The model also predicts the path loss better at a higher CPE height, which is consistent with the discussions in terms of accuracy of path loss exponent prediction (Table 5).

In the open urban environment, the standard deviation of error between measured and predicted path loss ranges from 0.01-0.1dB and 0-1.8dB for CPE heights of 2m and 4m respectively. At CPE height of 2m, the accuracy of the prediction increases as the distance increases between the CPE and the transmitter. At CPE height of 4m, the standard deviation of errors increase as distance from the transmitter is increased, indicating that the path loss prediction accuracy reduces when the CPE is further away from the transmitter.

For both models, the accuracy of the optimised models in predicting the path loss shows superior performance to that of the COST-231 Hata model. The standard deviation of error analysis for the COST-231 Hata model (Table 6) shows that the error range of the COST-231 Hata models is between 29-39dB for suburban environments and 25-34dB for open urban environments.

7. Contribution and uniqueness of work

This paper outlines how an optimised model for the prediction of path loss for WiMAX signal in the 2360-2390MHz band is developed based on measured field strength in Cyberjaya, Malaysia. After the comparison with measured path loss against theoretical path loss values was done, the best model was developed based on the existing COST-231 Hata model. This model was selected for the optimisation of the measured data because the path loss exponents estimated by the COST-231 Hata model was the closest to the measured path loss exponent. The developed optimised model was validated against the measured field strength, and was found to predict path loss in this band with higher accuracy than the COST-231 Hata model.

The development of these optimised models are crucial because the COST-231 Hata model is developed for the prediction of path loss for up to 2000MHz. Given the emphasis for broadband deployment in Malaysia, the optimised model presented in this paper can be used to predict path loss in the 2360-2390MHz for WiMAX signals with high accuracy.

8. Recommendation for future research

In this study, field data is only available for CPE heights of up till 4m. Future works can be done by collecting field data for greater CPE heights to verify the accuracy of the proposed optimised model in suburban and open urban environments. The field strength can also be collected in a typical urban environment, and similar methods can be employed to optimise a model based on COST-231 Hata, if found to be applicable, in the 2360-2390MHz band for the prediction of WiMAX path loss. The proposed method can also be applied to optimise a new model for the prediction of path loss experienced by mobile WiMAX systems.

9. Conclusion

Field strength of WiMAX signals in Cyberjaya is collected using a fixed WiMAX receiver and translated into path loss. The WBSs of the BS covers a mix of suburban and open urban environments. Open urban environment is less urban than a typical urban environment. The measured path loss, when compared against theoretical values from the SUI, COST-231 Hata and Egli path loss models, showed the closest agreement with the path loss predicted by the COST-231 Hata model in terms of path loss exponent prediction and standard deviation error analysis. Based on this, an optimised Hata model for the prediction of path loss experienced by WiMAX signals in the 2360-2390MHz band in suburban and open urban environment is developed. The optimised model showed high accuracy and is able to predict path loss with smaller standard deviation errors as compared to the COST-231 Hata model. It should be noted that the optimised models have a very small operating frequency range, which is between 2360-2390MHz only. Thus, the models were optimised to be independent of the operating frequency and the height of the BS, as long as the path loss estimation is done within the stipulated operating frequency range.

Table 6. Standard deviation of errors between measured path loss with COST-231 Hata path loss and measured path loss with optimised model predicted path loss

2m, CPE height 2m; 4m, CPE height 4m; CPE, Customer Premise Equipment

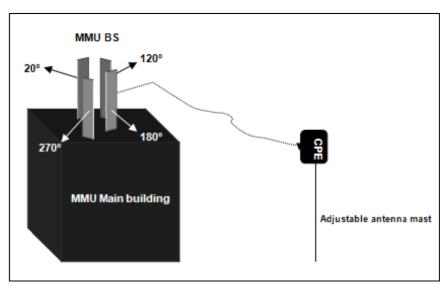

Figure 1. Experimental setup for field testing

MMU BS, MMU Base Station; CPE, Customer Premise Equipment; 20°, 120°, 180°, 270°, WiMAX Base Station azimuths

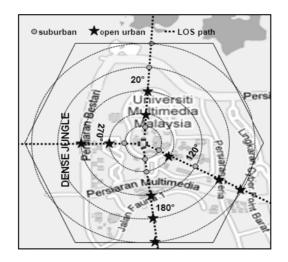

Figure 2. The estimated coverage area of the MMU BS and the LOS path of each WBS. LOS, Line of Sight

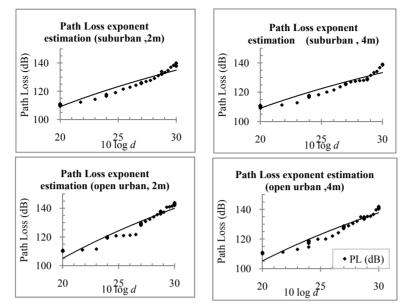

Figure 3. Path Loss (dB) versus distance (m) for open and suburban environments with CPE heights 2m and 4m

PL, path loss; d, distance from transmitter (m)

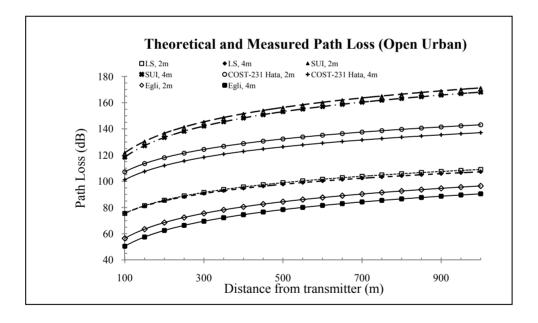

Figure 4. Comparison of measured and theoretical path loss in open urban environments for CPE heights of 2m and 4m

LS, Least Square (measured path loss); SUI, Stanford University Interim model; Egli, Egli model; COST-231 Hata, COST-231 Hata model; 2m, CPE height 2m; 4m, CPE height 4m

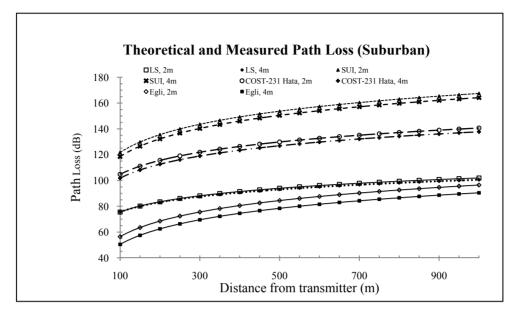

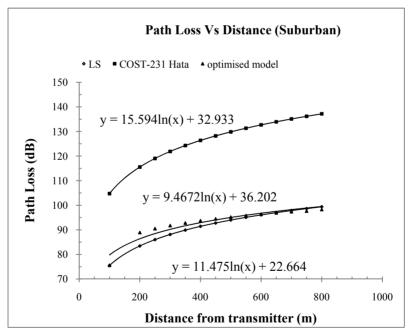

Figure 5. Comparison of measured and theoretical path loss in suburban environments

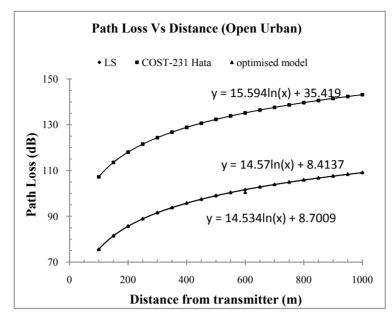

Figure 7. Development of optimised model based on COST-231 Hata model for open urban environment LS, Least Square model (measured path loss); COST-231 Hata, COST-231 Hata model

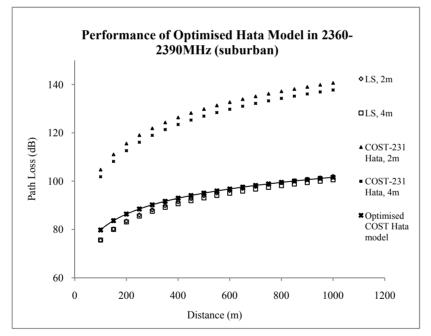

Figure 8. Comparison of path loss prediction by optimised model in suburban environment LS, Least Square model (measured path loss); **2m**, CPE height 2m; **4m**, CPE height 4m

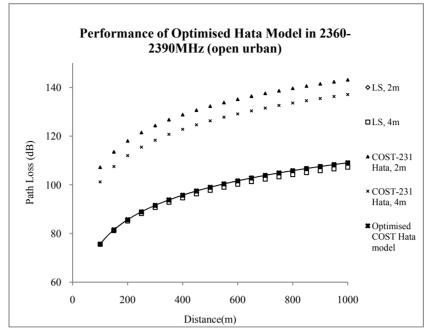

Figure 9. Comparison of path loss prediction by optimised model in suburban environment LS, Least Square model (measured path loss)

LS, Least Square model (measured path loss); 2m, CPE height 2m; 4m, CPE height 4m
